Preface

It is with great joy and much delight that I am finally completing this effort with these last few words. This research has been a tremendous learning experience, and for that reason, I value it. I do hope, though, that the work contained within this document proves useful to someone else. When that is the case, the total effort assumes additional significance because of the value others place in it.

My wife, Kathy, has been a blessing to me. When I grew up, I never envisioned starting my marriage by going back to school, yet alone to AFIT, where free time is a luxury. Kathy has supported me through it all, and I wish to dedicate this, and my love, to her.

The experiment would have taken much longer were it not for Ron Gabriel who consistently helped me find the equipment I needed. In addition, my good friend, Joe Gribble, provided valuable suggestions on how to improve this document. My sincere thanks to both.

Finally, I wish to thank my advisor, Maj. Jim Mills, who has provided me with important guidance and encouragement ever since I first entered the service 5 years ago.

J. C. Higgins

Abstract

This research effort measured the size of the optical signals scattered by highly specular spheres when illuminated by plane wavefronts. This was repeated for 13 different sized spheres so that the functional dependency on sphere size could be more accurately established. The experiment was conducted at $\lambda = 1.064 \mu m$ and at a fixed range of 731.5 cm in a bistatic configuration.

An analytical development based on geometric optics was used to predict the results. Within the limits of the small angle approximations, the results were generally within 10% of the measured values. The surface quality of the spheres and the alignment of the experiment were found to be the most critical variables affecting accuracy.

THE CONSTRUCTION AND CALIBRATION OF A LADAR CROSS-SECTION MEASUREMENT RANGE

I. Introduction

thesis
The purpose of this ~~research~~ was to construct an experiment that can accurately determine a target's laser radar cross-section. A "laser radar cross-section" (LRCS) is a measure of the average amount of optical power scattered by a target, and is analogous to the term "radar cross-section" (RCS), which is defined for scattered power radiating at microwave wavelengths. Cross-sections, whether optical or microwave, are quantities which describe the effective area of a specific target which directly scatters an incident electromagnetic (EM) wavefront. The focus of this thesis is to investigate the nature of LRCS measurements, with particular attention paid to the measurements of spherical calibration targets. *Key words: laser radar cross-section, spherical calibration targets, laser radar cross-section, laser radar cross-section, laser radar cross-section*

Background

production of LADAR (laser Detection and Ranging)
Radio Detection And Ranging (RADAR) devices are probably the best known of all man-made active detection systems. They are members of a larger group known as remote sensors, which include systems either man-made or biological, active or passive, and finally, electromagnetic or ultrasonic. Remote sensors are sensitive tools which can detect a signal, traveling freely through a medium, whose source is some finite distance away. These sensors are considered "passive" if their supporting systems don't illuminate the target. Instead, passive sensors detect emissions and reflections that are characteristic of the target;

the human eye is an example of a passive detector. By contrast, active sensors transmit a particular type of waveform, and then detect and interpret that small part of the reflected signal which returns. Radar and sonar (SOUND Navigation and Ranging) systems are examples of active detection schemes.

Radar. Radar devices were one of the more significant consequences of investigations into the response which specific materials had to an incident EM field (Skolnik, 1962:8-10). These scattering and diffraction studies eventually centered around the microwave frequencies which are now characteristic of radar devices. The notion of a scattering cross-section developed from these studies, and can be defined in fundamental terms as the ratio of the power scattered, per unit solid angle, divided by the incident flux (AFAL-TR-75-116:3). It is a function of many parameters, among which are the reflectivity at microwave wavelengths and the size, shape, and texture of the reflecting surface. The RCS parameter has the dimensions of area, and can be expressed by

$$\sigma_R = \frac{(\text{POWER REFLECTED TOWARDS SOURCE} \text{ / UNIT SOLID ANGLE})}{(\text{INCIDENT POWER DENSITY} \text{ / } 4\pi)} \quad (1)$$

For all but the most symmetric targets (i.e., a sphere or a flat plate), the cross-section does not bear a simple relationship to the physical surface area, except that the larger a target is, the greater the cross-section is likely to be. The significance of cross-section is directly tied to its linear relationship with the power of the return signal captured by the radar system's receiving antenna:

$$P_r \text{ (radar)} = \frac{P_t G_t A}{(4\pi R^2)^2} \sigma_R \quad (2)$$

(not accounting for atmospheric attenuation)

where

- P_r = return signal power (detected by the radar)
- P_t = radiated signal power (at the output of the device)
- G_t = power gain due to the antenna's directionality
- A = effective capture area of the antenna

Eq (2) is the primary form of the radar range equation, the importance of which lies in its ability to describe the maximum radar range at which a target can just be detected. This R_{\max} can be calculated when the minimum value of P_r is known for the detector system (Skolnik, 1962:4).

Laser Radar. With the introduction of the laser in 1960, it became possible to apply the fundamentals of radar theory to the optical regime of the EM spectrum. The end product was a laser radar, which illuminates the target with a coherent, monochromatic beam of light and then, like its microwave predecessor, detects the scattered return signal. Using Bachman's definitions, laser radar will now be referred to as "LADAR" (LAsER Detection And Ranging) (Bachman, 1979:2). Ladar systems currently being researched include those operating at $10.59\mu\text{m}$ and at $1.06\mu\text{m}$ (i.e., those with CO_2 and Nd:YAG laser sources, respectively). Much like its radar counterpart, there is a LRCS associated with every target, and it can be expressed by

$$\sigma_L = \frac{(\text{POWER REFLECTED TOWARDS SOURCE} / \text{RETURN SOLID ANGLE})}{(\text{INCIDENT POWER DENSITY} / \text{TOTAL RERADIATED SOLID ANGLE})} \quad (3)$$

Likewise, the power captured by the ladar system's receiving optics is described by

$$P_r (\text{ladar}) = \frac{P_t A_c}{\Omega_i \Omega_r R^4} \propto \quad (4)$$

(not accounting for atmospheric attenuation)

where

P_r = return signal power (detected by the ladar)

P_t = radiated signal power (at the output of the device)

Ω_i = incident solid angle (measured from the ladar to the target)

Ω_r = receiver solid angle (measured from the target to the ladar)

A_c = receiver clear aperture area

(Bachman, 1979:9-10). This is the primary form of the ladar range equation, which, like the radar range equation, provides important information for the definition of the maximum ladar range at which a target can be detected.

Significance of Range Equations. The previous equations provide much insight into the effect that various parameters, including a target's optical and microwave cross-sections, have upon the performance of both ladar and radar systems. The engineers who design these two types of systems can control, to some extent, all of the variables, except for the target's cross-section. Even the varying effects of the atmosphere can be somewhat compensated for. If, in fact, all of the other parameters in these two equations were equal, range performance at any particular wavelength would depend only on the target's cross-section at that wavelength. For this simplified scenario, a comparison of these cross-sections would be very important to the U.S. Air Force. Success in the ongoing effort to significantly reduce a target's radar

cross-section may not have a proportional effect on its optical cross-section. There is reason to believe that a target's LRCS may remain unchanged, or even grow larger, as its RCS is reduced. Open source publications (unclassified) have stated that "the Lockheed SR-71 Blackbird, a forerunner in the application of 'stealth' technologies, has been known to become visible to the unaided eye before becoming visible on radar" (Schefter, 1983:61). If this "visibility" also exists at a useful laser wavelength, then ladar systems may detect hostile targets at ranges much greater than their microwave counterparts are capable of. Furthermore, this information would be significant in the evaluation of future designs of out nation's own stealth aircraft.

Thesis Objective

The primary objective of this entire effort was to design and build an experiment capable of quantitatively measuring a target's LRCS. Since the definition of cross-section, as seen at optical wavelengths, is not presently standardized within the scientific community, a clear definition was chosen. The first of three specific goals involved the theoretical examination of the LRCS to be expected from a highly reflecting sphere. This investigation examined the backscattered return signal from such spheres in terms of both geometric optics and wave optics; furthermore, an attempt has been made to predict, using geometric optics, the actual size of the signal expected in a laboratory measurement. The second goal comprised the construction, refinement, and execution of an experiment (using a pulsed Nd:YAG laser at $1.064\mu\text{m}$) which can reliably measure a specific target's LRCS at normal incidence. The usefulness of this LRCS Measurement Range depended greatly on a

proper prior evaluation and control of experimental errors. The final goal actually consisted of making LRCS measurements of high quality spheres and then comparing these results with the predictions made by the geometric optics model.

Scope

This thesis effort was limited to considerations of only optical cross-section measurements which are a function of the spherical target's radius, alignment, and range. The geometry of a target usually plays a very important and complicated role in these measurements; spherical shapes, however, have no preferred orientation provided that the substance is optically isotropic. This makes the sphere an ideal geometry for the investigation of LRCS measurements. The design of the experiment dictates that all targets will each be measured at the same position, a distance of 7.3 meters from a known reference point on the experimental table and along the laser's optic axis. All the measurements were conducted in the laser's far field, and the assumption was made that careful control of the experiment could ensure that the targets were overfilled by plane waves of constant irradiance.

Atmospheric attenuation is a serious problem in quantifying the performance of an operational LADAR system. Its effects, however, were not considered in this research; furthermore, they were literally calibrated out of the experiment before each LRCS measurement was made.

General Approach

The second thesis goal that is stated on pg 5 involves construction of a working laser radar cross-section measurement range. Chapter II discusses the organization and layout of such a range. The individual

components of the experiment are described, and in some cases, justified. The emphasis is on the impact that certain design considerations have on the quality of the data obtained.

Chapter III addresses the theory of laser pulse scattering from a highly reflective spherical target. A model of the interaction is described, in terms of geometrical optics, and then predictions of the experimental results are made. These numeric predictions are tabulated in Appendix B. Finally, a model based on physical optics is recommended. A reference is made to Appendix C where a detailed but incomplete model of the experiment, using the Huygens-Fresnel theory, is presented.

The techniques used to prepare and properly conduct the experiment are presented in Chapter IV. The alignment process will be reviewed, but not covered in detail. Attention is focused primarily on the problems unique to the experiment, the control of errors, and the subtle pitfalls to be avoided.

In Chapter V, the experimental measurements are presented and then analyzed in terms of the geometric theory developed in Chapter III.

Conclusions and recommendations are offered in Chapter VI. An appraisal of specular spheres as LRCS Calibration Standards is made. Finally, recommendations for future study are presented with emphasis on problems relating to the collection of accurate LRCS data.

II. EXPERIMENTAL SETUP

The experimental measurement of the LRCS of many targets is of significant importance. The optical properties of some radically new materials cannot be accurately predicted based on theoretical calculations alone. With a need for precise knowledge of LRCS signatures, let us now consider what is required in terms of equipment, and its performance, in order to operate a LRCS measurement range.

Format of the Measurement Range

A schematic of the range is depicted in Fig. 2.1 and Fig. 2.2. A pulsed Nd:YAG laser operating at a wavelength of $1.064\mu\text{m}$ is the source of the emitted optical wavefront. This wavefront first passes through a negative lens, for reasons that will soon be explained. The wavefront next strikes a microscope slide, which is being used as a beamsplitter. This microscope slide partially reflects, towards the first of two detectors, a small portion of the energy contained in the incident wavefront. This detector, in turn, responds by emitting a representative electrical signal which is used as a reference trigger for the data collection equipment. Most of the original wavefront continues to propagate beyond the microscope slide and then, in the laser's far field (7.3 meters from the reference point), overfills the target. Depending on the target's size, shape, orientation, and backscatter characteristics at $1.064\mu\text{m}$, some part of the incident wavefront scatters back towards the source. It is the sensing of this return optical energy which constitutes "detection of the target." The amplitude of the

Fig. 2.1. LRCS Measurement Range (Plan View)

Fig. 2.2. The Emitter-Receiver Set-Up
(Enlargement of Region Encircled in Fig. 2.1)

return signal is linearly related to the LRCS of the target. In order to enhance the sensitivity of these measurements, intermediate optics are used to capture a larger portion of the backscattered signal and then converge this signal so that it just fills the smaller active region of a second detector. Under ideal conditions, the entire target should be imaged by the intermediate collecting optics onto most of this detector's active area. This approach would guarantee that the signal-to-noise ratio (SNR) is maximized within the limitations imposed by the target's geometry. The electrical signal generated by this second detector is displayed either on the CRT screen of a very fast storage oscilloscope, or when more detailed analysis is required, on the display of a complex signal processor which has been integrated with a boxcar averager.

In this experiment, the line of sight of the laser illuminator is not the same as the line of sight of the detector's collecting optics. This non-coaxial configuration is commonly referred to as a "bistatic" system. Although the data generated by this arrangement is much more sensitive to alignment errors in the target's position, it benefits from a higher SNR than could be achieved in a coaxial configuration, all other factors being equal. A coaxial configuration, in which both the EM wave transmitter and receiver have the same field of view, is commonly referred to as a "monostatic" system.

Two independent Helium-Neon (HeNe) lasers are simultaneously used to ensure that each target is placed in the one spatial position that is exactly centered within the field's-of-view of both the laser and the return signal's collecting optics. One laser is co-aligned to the Nd:YAG laser's line of sight, while the other HeNe laser is co-aligned

with the optic axis which passes directly through the collecting optics. It is where these two reference beams superimpose on one another that the target's surface must be located.

Characteristics of the Nd:YAG Laser

One of the factors which most affects the intensity distribution of the return signal is the target. Equally important, though, is the intensity distribution of the incident signal (which is then scattered in a unique way by the target). For this reason, that incident signal should be well characterized. Under ideal conditions, the incident wavefronts would be planar with a uniform constant amplitude across their surfaces. Every effort has therefore been made to approximate this ideal condition.

The Nd:YAG laser chosen for this project was an International Laser System's (ILS) model LL-102-20. It was selected because of its rather short pulsewidth, a nominal 30 nsec full-width-at-half-maximum (FWHM). This size pulsewidth is short enough in duration to allow temporal distinction between a return signal from a target and that from background clutter located only 5 meters beyond the target. (5 meters separation equates to 10 meters round trip optical path length; at the speed of light, this distance is traveled in approximately

$$\frac{10 \text{ METERS}}{3 \times 10^8 \text{ METERS/S}} = 33.\overline{33} \text{ nsec} \quad (5)$$

which is a peak-to-peak separation that certainly satisfies the Rayleigh criteria for resolution of two consecutive pulses.) Had the pulse width been much shorter in duration, its size would have approached the "read"

rate of the data collection equipment. The error bars associated with those measurements would have been unacceptable.

An optical schematic of the laser is presented in Fig. 2.3. The resonator optics consist of two porro prisms which are oriented 90° from one another about the cavity's optical axis. In other words, the roof edges of each prism are perpendicular to one another. The Nd:YAG laser rod measures 5 mm in diameter by 75 mm long and is optically pumped by a Xenon flashlamp. Q-Switching of the laser is performed by a Pockels Cell. A dielectric polarizer is sealed between two right angle prisms which are joined symmetrically to form a cube (see Fig. 2.3). In this "cube," the right angle prism closest to the YAG rod is responsible for partially coupling out the laser pulse from the cavity. Two additional lenses found within the resonator expand the beam and compensate for positive focusing that occurs within the laser rod. An adjustable iris also exists within the cavity for control of higher order modes (ILS Operation, Maintenance, and Service Manual, 1979:2-10).

During the experimental build-up, the iris was slowly closed until the output beam appeared to have a gaussian irradiance distribution (as viewed on photosensitive paper). At this point, the diameter of the iris was $2.955 \pm .003$ mm and the energy in each pulse was certainly less than the .1 joules (J) expected with the iris completely open. The average of 10 measurements, listed in Table 2.1, indicate that the average pulse energy is in fact $.0166 \pm .0003$ J. Since the limiting aperture in the cavity is the iris, it is reasonable to initially assume that the spot size at this point is the waist, w_0 , of the laser. If the two compensating lenses were not also within the cavity, the calculation of the Rayleigh range could be done accurately:

Fig. 2.3. Optical Schematic of the Nd:YAG Laser

1 - .0167 J	6 - .0161 J
2 - .0163 J	7 - .0169 J
3 - .0164 J	8 - .0163 J
4 - .0170 J	9 - .0167 J
5 - .0168 J	10 - .0169 J
MEAN VALUE = .0166 J MEDIAN VALUE = .0167 J STANDARD DEVIATION = .0003 J	

Table 2.1. Measurements of Pulse Energy

$$\text{RAYLEIGH RANGE} = \frac{\pi w_0^2}{\lambda} \quad (6a)$$

$$Z_R = \frac{\pi (1.477 \text{ mm})^2}{(1.064 \times 10^{-3} \text{ mm})} \quad (6b)$$

$$Z_R = 6.44 \text{ METERS} \quad (7)$$

Because of the effects of the compensating lenses, the Rayleigh Range is actually larger. This means that at a range of 6.44 meters from the location of the waist, a target would not yet be located within this laser's far field. The spot size at the laser's output is $1.58 \pm .02$ mm. Since it is reasonable to presume that this value is larger than

the effective waist of the cavity, a sufficient upper limit for z_R can now be computed. Using Eq (6a), the Rayleigh Range is found to be less than 7.37 meters. The importance of this is that, in the far field, the rate of divergence of the laser wavefront is constant. Measurements of the two spot sizes in the far field indicate a far field half angle of 4.48 milliradians. Since all of the targets will be measured at a range of 7.3 meters, careful measurements of the irradiance distribution of a pulse were made at this range. This data was gathered by slowly translating a photodiode detector (masked by either a .20 mm or a .50 mm slit) along a path perpendicular to and intersecting the Nd:YAG laser's optical axis. A number of measurements of local irradiance were made for each detector location and for each of the two slits. The plots of the average pulse irradiance profile are depicted in Figs. 2.4 and 2.5, and error bars are provided for each measurement made. Although the large size of the error bars associated with the most intense central points prohibit precise identification, the expected gaussian transverse-amplitude variation across the pulse's wavefront fits the profile. As a consequence of the Q-switching method employed, the laser light is also linearly polarized with its electric field vector aligned along the horizontal axis.

The Diverging Lens

The target's return signal can be best interpreted if there is some margin of consistency across the wavefront which first strikes the target. Although the ideal condition (i.e., a perfectly plane wave with a uniform constant irradiance) can never be realized, a very good approximation of this can be achieved with the proper choice of a negative

Fig. 2.4. Nd:YAG Pulse Spatial Irradiance Profile (.50 mm slit)
(Amplitude Attenuated by 4.00 N.D. Filter)

Fig. 2.5. Nd:YAG Pulse Spatial Irradiance Profile (.20 mm slit)(-600 mm F.L.
Diverging Lens Installed at Laser Output)

lens at the laser device's output. Because a gaussian spherical wave is essentially emitted by the laser, the pulse's most central region is much like a plane wavefront of constant irradiance. Unfortunately, the region within which this is true is also very small. By diverging the emitted beam, this acceptable central region can completely overfill the target. The only penalty paid is a reduction in the amount of optical energy available to be scattered. A judicious choice of a bi-concave, -600 mm focal length lens resulted in an acceptable central region of diameter 3.55 cm at the designated 7.3 meter range.

Spheres as Calibration Standards

A single definition of a LRCS has not been universally accepted throughout the scientific community. This is consistent with the disagreement over the form of the laser radar range equation. A cross-section, at any frequency (whether microwave or optical), is a convenient parameter for characterizing a target. It should be described by a single numerical value which is a function of the static properties (i.e., size, shape, composition, etc.) and, if applicable, the dynamic properties of the target (Bachman, 1979:52-56). This single numerical value directly relates the LRCS for the unknown target to that for a very well characterized standard. Herein lies the disagreement concerning the LRCS definition. Two different calibration standards exist for LRCS measurements, and each has served a purpose by describing the size of the return signal to be expected from targets of similar composition. The first standard, a theoretically lossless diffuse flat plate, is the most commonly used (Wyman, 1968:1). For this reference, the LRCS of a

target is defined as "the area of a non-absorbing, planar, perfectly lambertian surface which, when substituted for the target and oriented perpendicular to the ladar line-of-sight, produces a scattered irradiance at the receiver equal to that of the target. (Common experimental approximations to the diffuse standard include such surfaces as magnesium oxide and flame-sprayed aluminum)" (Bachman, 1979:184). The second standard sometimes used is an "isotropic specular sphere; that is the target's LRCS can be considered to be the equivalent cross-sectional area of a perfectly reflecting specular sphere which produces a reflected intensity at the receiver equal to that of the unknown target. It can be shown that the intensity from a spherical reflecting surface is given by

$$I(z) = \frac{I_1 R^2}{4 z_1^2} = \frac{I_1 A_{cs}}{4 \pi z_1^2} \quad (8)$$

where

I_r = reflected intensity

I_1 = incident intensity

R = radius of the spherical surface

z_1 = the range from the spherical surface

A_{cs} = the spherical surface's cross-sectional area"

(Bachman, 1962:183-184).

Two different calibration standards are not necessary. Only one is ever required, and its two utmost criteria need only be its consistency and availability. It is the spherical standard which, although more difficult to preserve as a high reflector, has become the highlight of this experiment. This is in terms of both its use as a reference target for other LRCS measurements and as a theoretical scattering problem to be examined and better understood. This latter investigation is, in

fact, the entire subject of Chapter III.

Very high grade steel ball bearings of 13 different sizes have been selected to represent the highly reflecting spheres in the experiment. Although there is little information on their nominal reflectivity at $1.064\mu\text{m}$, it can be assumed to be greater than 95%. Produced by Hoover Universal Inc. of Cumming, GA., they are of grade "5" with a deviation from sphericity of no more than 5×10^{-6} inches (Hoover Universal, 1983). The diameters of the test spheres, measured in inches, are: $1 \frac{1}{4}$, $1 \frac{1}{16}$, $\frac{15}{16}$, $\frac{3}{4}$, $\frac{11}{16}$, $\frac{5}{8}$, $\frac{1}{2}$, $\frac{7}{16}$, $\frac{3}{8}$, $\frac{5}{16}$, $\frac{1}{4}$, $\frac{3}{16}$, and $\frac{1}{8}$.

Collecting Optics

Some targets will have a very small LRCS at $\lambda = 1.064\mu\text{m}$. It was therefore determined that the detector available might not be sufficiently responsive. Four alternatives existed:

- 1) a photomultiplier tube (PMT) with inherently high gain could be used instead of the fast photodiode selected,
- 2) the range could be reduced,
- 3) the energy in the incident laser pulse could be increased or,
- 4) more of the return signal could be captured and then concentrated on the photodiode.

A PMT would have been awkward to align and more cumbersome to use. Shortening the range would have moved the target's location into the laser's near field. Upgrading the laser's pulse energy would have been unnecessarily time consuming. Only in the last choice was there both simplicity and a second benefit. By using a variable focus telescope (see Fig. 2.6) to collect a bigger portion of the backscatter signal,

Fig. 2.6. Schematic of Collecting Telescope
(no additional technical information is available)

the photodiode's field of view could also be controlled. By imaging the entire target (and as little else as possible) onto the active region of the detector, the chances were minimized that stray energy from other reflections would feed back into the photodiode. Built by Special Optics Inc., the telescope contains four refracting elements and was designed for high transmissivity at $1.064\mu\text{m}$ with only $\lambda/10$ wavefront distortion.

Signal Detection

The LRCS measurement range required two detectors: one to trigger the signal recording equipment, and a second to actually measure the return signal. The device selected for both applications was an ultra-fast silicon photodiode called the FND-100. Produced by EG&G, it rivals a PMT in performance except that it does not provide low noise signal gain. Its characteristics are listed in Table 2.2 and its spectral response is plotted in Fig. 2.7. It has a circular active area of 5.06 mm^2 (smaller in size than the 19.63 mm^2 exit lens of the collecting telescope) and is a unit compact enough to be physically translated by a micrometer in two dimensions. The spectral response curve indicates that approximately $.253 \pm .005$ amps/watt can be expected from the FND-100 at $\lambda = 1.064\mu\text{m}$ but care must be used to ensure that the return signal does not overfill the active area on the photodiode's front face. The details of the alignment that guarantees this condition are presented in Chapter IV. Uniform neutral density filters were employed to ensure that each photodetector would be performing well within its linear operating region.

Active area	= 5.1 mm ²
Wavelength	= 300-1100 nm
Bandwith	= 350 MH
Responsivity	= 0.62 A/W @ 900nm
Rise time (10-90%)	= 1 nsec @ 50
Breakdown Voltage	= 125 V
Capacitance	= 8.5×10^{-12} F
Series Resistance	= 35 ohms
Dark Current	= 100 namps
Noise Current	= 1.8×10^{-13} amp/Hz ^{1/2} @ 1 KHz
NEP	= 2.9×10^{-13} W/Hz ^{1/2}
Operating Temperature	= -55 to +70° C
Linearity	= ± 2% over 7 decades

Table 2.2. Typical Performance Characteristics of the FND-100
With a 90 Volt Bias (EG&G Data Sheet D3013b-1)

Signal Storage and Processing

When optical energy strikes the active region of the FND-100, a representative electrical signal is generated with a rise time of 2-3 nsecs. This signal travels through 2 meters of RG-58 coaxial cable to the data storage instrument which has an input impedance of 50 Ω . Provided that the instrument has been properly triggered to begin writing a time-history of the electrical voltage that it receives, the CRT screen will display the pulse. Herein lies a common difficulty with

Fig. 2.7. FND-100 Absolute Spectral Response
(EG&G Data Sheet D30138-1)

measurements of very short laser pulses. Non-laser optical energy is generated by the flashlamp long before the laser pulse is created. This non-laser energy is first detected and can trigger the writing function of the data storage equipment; these events unfortunately occur much too soon for any useful laser pulse information to be recorded. The solution to this dilemma involves the use of narrow bandpass filters, each with a maximum transmittance at $\lambda = 1.064\mu\text{m}$ and a bandwidth of only 52 Å. These filters, positioned across the entrance to the photodiodes, seal out all spurious non- $1.064\mu\text{m}$ light. Although flashlamp emissions exist at $1.064\mu\text{m}$, the intensity is purposefully below the trigger's thresh-

old.

The first of two types of storage equipment used are a Tektronix Storage Oscilloscope (Model #7834) with two plug-in modules: a Dual Trace Amplifier (Model #7A26) and a Dual Time Base (Model #7B53A). This unit provides a quick and accurate record of a single pulse's temporal profile. As such, it is the workhorse for all alignments and quick measurements. The second data storage system used is an EG&G Model 4400 signal processing system, composed of a Boxcar Averager (#4420), a Gated Integrator (#4422) and the actual signal processor (#4402). The system, although much more time consuming to use, is capable of performing an indepth analysis of the scattered energy which is measured by the second FND-100. Its CRT display is identical to that of the oscilloscope's in format. The 4400 system's display, however, is not a continuous function, but rather is broken up into a series of discrete points. Each point represents the average value of the signal measured across a small interval of the pulse, The penalty for this type of operation is paid in terms of time and laser stability. Many pulses are required (one for each discrete point) in order to profile an "average" pulse. This averaging operation is only useful when laser stability has been achieved. Nonetheless, the 4400's supporting software provides post-data acquisition processing which is unavailable on an oscilloscope.

Background Reflections

Almost every material reflects some energy at $\lambda = 1.064 \mu m$. Although this is generally a desired feature in a ladar system, it can also be a source of errors if calibrated measurements are to be made.

It is therefore of the utmost importance to identify and control the undesired reflections which can feed back onto the signal detector.

"Even very small ladar signals can become detectable by filtering out as much optical background clutter, or noise, as possible. The filtering can be spatial, temporal, or spectral" (Bachman, 1979:88), but this ladar measurement range uses a combination of all three of these methods.

Spatial filtering was employed through the use of the collecting telescope which, by its very nature, significantly reduced the signal detector's field of view from its original 2π steradians. By selecting a field of view that just included the target, the influence of many significant sources of unwanted backscatter was eliminated. Some inescapable sources of clutter were still within this limited field of view; these included the rear wall of the laboratory and the support structure for the targets.

The location of the wall could not be changed, and surprisingly enough, its return could only be marginally reduced by shrouding the wall with other absorbing materials. Bachman, in a short commentary on LRCS measurement ranges, suggested hiding the effect of the wall with "an ordinary glass aquarium tank oriented at a skew aspect angle to the incident pulse and filled with water darkened by black ink." A better solution was found by the judicious use of temporal filtering. By moving the target in from the rear of the room so that it was now a good distance from the back wall (but still located in the laser's far field), the return from the wall was now distinguishable in time and separable from that of the target. By further orienting the experiment so that the incident and return line of sights were approximately 17°

from the wall's normal, the irradiance of that backscattered return was significantly reduced.

Spatial and temporal filtering were of little use in dealing with the return caused by the target's support structure. The use of cotton string to hold the spherical targets was desirable because of the string's almost negligible LRCS, but the ball bearings chosen as spherical standards required precise alignment. This could not be achieved and maintained using cotton string. Because of the hardness of the ball bearings, machining any portion of their non-irradiated hemisphere caused damage to their opposite surface. Because of the importance of high surface quality in this calibration, this operation was not considered, and non-vertical rigid support of the spheres was decided to be impractical. Although not ideal, the final choice for support structures were 6 cylindrical lucite rods with highly buffed surfaces. Only one rod, of smallest possible diameter and with one end spherically lapped to match a specific ball, was required for support. Each ball bearing of different size was assigned to the smallest lucite rod which would support it. These rods had a reflectivity at $1.064\mu\text{m}$ of approximately 7.5% (U.S. Precision Lens, Inc., 1973:17), and the small portion of the incident pulse which was actually reflected back into the capturing telescope was very small. Multiple reflections, although possible, were not considered probable. The most convincing argument is, by far, made by comparing the return from a supported sphere and that from just the rod (when the sphere has been removed). The return from the rod alone is, on average, only responsible for 15% of the net measured signal.

The temporal profile of the return signal should consist of two

consecutively positioned peaks, the first from the target and of much greater magnitude than the second, which is due to the wall. With the careful location of a vertical aluminum rod near, but not in, the main beam path, a third small peak can be introduced to the profile. It precedes the others mentioned and represents a reference for the outgoing wavefront as it leaves the experimental table (see Fig. 2.8). The final temporal profile is then composed of three peaks, all with the same generic shape but with vastly different profiles (see Fig. 2.9). The first and last of the three pulses provide convenient reference marks throughout the measurement process for the location of the expected LRCS returns.

Fig. 2.8. Schematic of Experimental Table Identifying Reference Signal Feedback Mechanism

III. Laser Pulse Scattering Theory

An Overview of the Analytic Developments

In order for a highly reflecting sphere to be used as a standard against which other LRCS measurements are made, its own LRCS must first be defined. Historically, this type of requirement has repeatedly generated the same controversy: against what should the "standard" itself be standardized?

The general approach to avoid this dilemma has typically involved simplifying the problem, by identifying the specific relationship that exists between the standard and the magnitude of its return signal. This relationship blindly accomodates all of the experimental constants which, if varied, would affect each measurement. Accounting for each of the experimental constants would be the first step towards calculating the absolute size of the return signal expected at the detector. The list of experimental constants is quite large, and includes the ladar beam's degree of coherence, its profile, wavefront curvature, and size relative to the target. It can include polarization (if the detector is polarization sensitive), and atmospheric distortion and absorption. In fact, the list contains so many different parameters that complete theoretical characterization of a target may not be possible. It is for this reason that the historical approach has been to universally define the LRCS of a perfect specular sphere to be, in the far field, the geometric projected area

$$\sigma_L (\text{SPHERE}) = \pi a^2 \quad . \quad (9)$$

where "a" is the sphere's radius. This definition is independent of both polarization and bistatic angle (Danielson, 1977:17).

Despite the complexity involved, every attempt should be made to predict the size of the return signal expected when a sphere is the target. Correct analytical expressions for this return signal amplitude provide a basis for further theoretical analysis of some more complex targets. A mathematical approach to the problem of backscattering from a sphere is developed in this chapter. Using the techniques of geometric optics, it is a very good approximation because the sphere's smallest dimension is so much greater than the wavelength of the incident light. A superior approach uses physical (or wave) optics in a more precise treatment of the problem. This derivation is performed in detail in Appendix C, but final numeric predictions are not made. The exact solution of the wave equation for scattering of a plane, linearly polarized monochromatic wave by any homogenous sphere of arbitrary size was derived by Gustav Mie in 1908 (Asano and Yamamoto, 1975:29).

Although it is a classical work, seemingly of great significance to this effort, Mie scattering theory will not be applied to this specific problem. His theoretical solution is expressed, in series form, in terms of Legendre polynomials and spherical Bessel functions (Stratton, 1948:VI). For particles of the same order size as the incident wavelength, only the first few lower order terms of the series are of appreciable magnitude. As the ratio $\alpha = 2\pi a / \lambda$ increases (where "a" is the sphere's radius and " λ " is the spectral wavelength), many additional terms assume importance. "The evaluation of the Mie formula when only a few terms are considered is computationally tedious and very time consuming. To date, tables of light scattering functions have been

compiled for values of α only up to 200. For $\alpha = 5000$, the calculation is a formidable task for even a so-called super computer" (Erteza, 1981:1005). The smallest sphere being examined in this experiment has a radius of curvature of approximately .16 cm. For this sphere,

$$\alpha = \frac{2\pi (.16 \text{ cm})}{1.06 \times 10^{-4} \text{ cm}} \approx 9484 \quad (10)$$

Many of the larger spheres have an α greater than 100,000. For this reason, the use of Mie's computations was not considered further.

A Model Founded on Geometric Optics

Geometric optics suggests that there is a one-to-one relationship between every reflecting point on the sphere's surface and every point within a community of points in the detection plane. The analytic relationship which will now be derived using ray optics will relate these two sets of corresponding points. Since the location of the collecting telescope's entrance aperture in the detection plane is well known, it is possible to determine the effective area on the sphere's surface which re-radiates energy measured by the detector. If a plane wave of constant amplitude illuminates the sphere, then the reflected energy captured by the telescope should be

$$E_{\text{EXPECTED}} = \mu A_{\text{eff}} \Gamma \eta \quad (11)$$

where

μ = energy density of the incident wavefront

A_{eff} = surface area of the sphere, projected onto a plane, which re-radiates that energy collected by the telescope.

Γ = reflectivity of the sphere at 1.064

η = single pass attenuation of the laser energy by the atmosphere

It will be assumed that both μ and Γ are constant values for all points on the sphere. Fig. 3.1 depicts the scattering problem in two dimensions. The greatest off-axis observation point, r_{max} , is 22.4 cm. At a fixed range of 731.5 cm, the greatest angle, 2θ , between an incident ray and its reflection can be determined by examining a limiting case. If nothing but the sphere's size could be changed, then the largest scattering angle (2θ) would be measured for an infinitely small sphere. This is because ρ would also be a minimum value, approximating zero. For this example, the largest possible angle is

$$\tan 2\theta_{max} = \frac{22.4 \text{ cm}}{731.5 \text{ cm}} \quad (12a)$$

$$= .030622 \quad (12b)$$

$$2\theta_{max} = .030612 \quad (13)$$

The numeric solutions have been displayed to six decimal places in order to demonstrate the following point. For the very small values of θ expected in this problem, small angle approximations will be quite valid.

$$2\theta_{max} \approx \sin 2\theta_{max} = (.030608) \quad (14)$$

Fig. 3.1. Two Dimensional Analysis of the Scattering
Problem Within the Geometric Optics Limit

(not drawn to scale)

$$2\theta_{\max} \approx \tan 2\theta_{\max} = (.030622) \quad (15)$$

and

$$\cos 2\theta_{\max} = .999531 \approx 1 \quad (16)$$

Using these approximations will generate a geometric error of no more than

$$\frac{(.030622) - (.030612)}{(.030622)} \times 100 = .03 \% \quad (17)$$

The collecting telescope's entrance aperture does not lie completely in the plane represented by $z=z_i$ (see Fig. 3.1). If no approximations were allowed, the aperture would have to be mathematically described as lying centered and tangent to the circle of radius $(z_i - a)$ and with center at $(0,0,a)$. Instead, because of the small angles and relatively long ranges involved, the aperture can be treated as if entirely within the $z=z_i$ plane. Referring to Fig. 3.2, the error associated with this approximation is calculated below.

$$\tan 2\theta = \frac{x}{(z_i - a) \sin 2\theta} \quad (18)$$

therefore

Fig. 3.2. Analysis of Telescope Alignment Error

$$x = (\tan 2\theta)(\sin 2\theta)(z_i - a) \quad (19a)$$

$$= \frac{\sin^2(2\theta)}{\cos(2\theta)} (z_i - a) \quad (19b)$$

The fractional error is

$$\frac{x}{[(z_i - a) / \cos 2\theta]} \times 100 = 100 \sin^2(2\theta) \quad (20)$$

Since $2\theta_{\max} = .030612$ rad, $\sin^2(2\theta_{\max}) = 9.036 \times 10^{-4}$, and the final fractional error is

$$100 (9.036 \times 10^{-4}) = .09 \% \quad (21)$$

Now that the necessary approximations have been justified for this short derivation, please refer back to Fig. 3.1. In order to evaluate r_c for every value of ρ in this two dimensional problem, we will follow an approach applied by Rome Air Development Center (Demma and Michels, 1971:19-20).

$$\sin \theta \approx \frac{\rho}{a} \quad (22)$$

$$\tan 2\theta = \frac{r_o - \rho}{z_i - a \cos \theta} \quad (23)$$

Applying the acceptable small angle approximations

$$\sin \theta \approx \theta \approx \frac{\rho}{a} \quad (24)$$

$$\tan 2\theta \approx 2\theta \approx \frac{r_o - \rho}{z_i - a} \quad (25)$$

Therefore

$$\frac{2\rho}{a} = \frac{r_o - \rho}{z_i - a} \quad (26)$$

$$2\rho(z_i - a) + \rho a = r_o a \quad (27)$$

$$\rho [2(z_i - a) + a] = r_o a \quad (28a)$$

and

$$\rho = \frac{a r_o}{2 z_i - a} \quad (28b)$$

Using this relationship, the effective reflecting area of the sphere must be determined. The effective area is not the same as the surface area that contributes to the measured signal. Instead the effective area is equal to the surface area projected onto the incident planar wavefront. It is this area, multiplied by the wavefront's energy density, which equals the maximum energy measured by the detector under ideal conditions [refer to Eq (11)].

The three dimensional problem is now depicted in Fig. 3.3. Fig. 3.1 is, in fact, a two dimensional slice of Fig. 3.3, describing the geometry only in the plane which includes the optic axis and, coincidentally, both the points (ρ, \emptyset, z) and (r_o, \emptyset, Z_i) . The points in the z_i -plane, bounded by the telescope's aperture, must now be mapped to the $z=a$ plane (see Fig. 3.4). The perimeter of the sphere's effective area can be determined by directly comparing it with the telescope's aperture. Because the mapping occurs according to Eq (28b), it is linear. Within the limits of the small angle approximations made, the map of a circular aperture will therefore also yield an effective area bounded by a circle. If, however, r_o were of a size significant compared to ρ , then the relationship between the two terms would become quite non-linear, and the effective area would be more or less "egg-shaped." This is demonstrated by a heuristic argument in Appendix A. The size of the circular effective area can readily be determined by comparing the corresponding on axis boundary points. Because

$$c-b < r_o < c+b \quad (29a)$$

Fig. 3.3. Three Dimensional Analysis of the Geometric Scattering

Problem in a Bistatic System

(not drawn to scale)

Fig. 3.4. Comparison of the Two Planes Between Which Mapping Occurs
(not drawn to scale)

$$11.6 \text{ cm} < r_0 < 22.4 \quad (29b)$$

$$\frac{11.6 a}{2(731.5 + a) - a} < \rho < \frac{22.4 a}{2(731.5 + a) - a} \quad (30)$$

For the largest sphere, $a = 1.587 \text{ cm}$ and

$$.013 \text{ cm} < \rho < .024 \text{ cm} \quad (31)$$

The effective reflecting area is therefore

$$\pi \left(\frac{.024 - .013}{2} \right)^2 = 1.0756 \times 10^{-4} \text{ cm}^2 \quad (32)$$

An estimate can now be made of the optical energy expected at the telescope's entrance. Measurements (see Fig. 2.5) indicate that the energy density at the sphere is on the order of $8 \times 10^{-5} \text{ J/cm}^2$. Assuming that the reflectivity (Γ) is a constant 98% at $1.064 \mu\text{m}$, and that atmospheric absorption (η) in the laboratory contributes another loss of no more than 1%, then Eq (11) predicts

$$E_{\text{EXPECTED}} = \mu A_{\text{eff}} \Gamma \eta \quad (11)$$

$$= (8.17 \times 10^{-5} \text{ J/cm}^2)(.98)(.99) \\ \times (1.07 \times 10^{-4} \text{ cm}^2) \quad (33a)$$

$$= 8.485 \times 10^{-9} \text{ J} \quad (33b)$$

If there were no absorptive losses during transmission through the telescope, and if the collected energy does not over fill the detector's active region, then the following electrical signal will be produced by the photodiode:

$$V'_{\text{peak}} = 50 \Omega \times (.253 \pm .005) \text{ A}/\omega \times \frac{8.485 \times 10^{-9} \text{ J}}{30 \times 10^{-9} \text{ sec}} \quad (34a)$$

$$V'_{\text{peak}} = 3.578 \pm .070 \text{ V} \quad (34b)$$

where

$(.253 \pm .005) A/\omega$ = the calculated performance of the detector at

$\lambda = 1.064 \mu m$

30 n sec = the average pulse width (FWHM)

50Ω = the data equipment's effective input resistance.

However, no refracting telescope is perfectly transmissive. It is a good assumption that the losses are probably within 2%, so Geometric Theory predicts that the temporal profile of the laser pulse reflected off of the largest sphere will have a peak amplitude of

$$V'_{\text{peak}} \times .99 = V_{\text{peak}}$$

$$(3.578 \pm .070) \times .99 = 3.542 \pm .069 \quad V \quad (35)$$

Predictions of the returns from each of the 13 different sized spheres that will be measured are presented in Appendix B.

A More Rigorous Approach

The scattering of light from a sphere, as mentioned earlier, is really a diffraction problem. Wave optics therefore provides the preferred approach to this problem's solution. In the geometric limit, it was acceptable to assume that the absolute intensity at a specific point in the telescope's aperture was due only to a reflection at a correspondingly unique point on the target sphere. This is only an approximation of the solution specified in the realm of physical optics. The absolute intensity at any specific point in the aperture is, in fact, due to a linear superposition of all of the complex-valued field amplitudes. Each of these amplitudes is the result of contributions by

all of the points on the sphere's exposed surface, and each is weighted by an obliquity factor as a function of location. This is just an extension of the Huygen's Principle, which states that "every point on a primary wavefront serves as the source of spherical secondary wavelets such that the primary wavefront at some later time is the envelope of these wavelets" (Hecht and Zajac, 1979:61). For the actual application of this approach, refer to Appendix C.

IV. Experimental Procedures and Control of Errors

This experiment measures optical signals, emitted from a less than ideal laser source, which then scatter from the surface of an imperfect sphere. The energy is collected by an absorbing telescope and quantitatively measured by a detector whose output must then be amplified. Although these constraints seem to make it difficult to obtain accurate results, the errors are easy to contend with on an individual basis. The statistical variation in amplitude across the laser pulse's wavefront has already been presented in Fig. 2.5. The absorption in the telescope has been estimated to be approximately 2% at $1.064\mu\text{m}$. The quality of the sphere, and the effects of amplification, will be discussed later.

The most difficult source of inaccuracies are those which result from mis-alignments. These errors are not as easily quantified and are, in fact, most easily addressed in terms of their net effect. This chapter will therefore present the techniques used to prepare and properly conduct the experiment. The alignment process will be reviewed, but not covered in minute detail; rather, attention will be given to unique problem areas and pitfalls to be avoided.

The Alignment Process

The bistatic nature of this measurement range (discussed on pg 11) complicates the process of collecting meaningful data. Each target sphere must be located in the unique spatial position that is exactly centered within the field's-of-view of both the laser and the collecting telescope. It is for this reason that the alignment of the telescope

and detector, and the alignment of the target, are inextricably linked. All of the following procedures can thus be fit into one of two categories:

- 1) those that are generic to all measurements, and
- 2) those that must be repeated for every new target.

Generic Procedures. The one constant in this experiment to which all other alignments will be referenced is the Nd:YAG laser's optic axis. This axis should intersect the diverging lens, the microscope slide, and the center of the target. With the lens removed, the microscope slide can be roughly adjusted to partially reflect the output laser pulse towards the trigger photodiode. Caution must be used because the output laser pulse is plane polarized along the horizontal axis. The nominal 45° - 50° angle that the microscope slide makes with the Nd:YAG optic axis is very close to Brewster's angle. This angle ($\sim 57^{\circ}$) must be avoided if signal detection is to occur. For this reason, the microscope slide should be fixed at an angle that supports a strong reflection, and then, the photodiode should be positioned to intercept the reflected pulse.

The co-alignment of a HeNe beam with the Nd:YAG optic axis is the next goal. The HeNe laser that supports this will henceforth be referred to as "HL1." It can be translated from side to side and adjusted in both azimuth and elevation angles. This flexibility is used to position HL1's beam at the precise point on the back surface of the microscope slide which intercepts the Nd:YAG optic axis. This alone will not ensure co-alignment of the two beampaths. The fold mirror (FM-1) identified in Fig. 4.1 must then be adjusted to center HL1's beam

on the Nd:YAG optic axis in the far field. The HeNe spot on the microscope slide will now be in error, so this alignment must again be repeated. The two parallel techniques must be iterated until both are simultaneously satisfied. It is then that the two beampaths are co-aligned. As a convenient check, the HeNe beam partially transmitted through the microscope slide should strike the trigger photodiode slightly left of its central region. This small displacement occurs because the Nd:YAG pulse and HL1's beam do not intercept the microscope slide's front surface at the same point. This is depicted in Fig. 4.2.

If the trigger photodiode is still positioned to intercept the Nd:YAG reflection, install an adjustable narrow band pass filter (see pgs.24,25) in front of the detector. Orient the filter so that it partially reflects HL1's beam back upon itself. When this is accomplished, heavy tape should be used to create a light-tight seal between the edges of the filter and the detector. The trigger photodiode is now both fully aligned and isolated from non- $1.064\mu\text{m}$ light. It, and the microscope slide, must not be further adjusted.

A range of 731.5 cm has been selected as a constant parameter of all the measurements. This is conveniently half the distance between the reference plane and the back wall of the laboratory. A piece of monofilament line, securely attached to the edge of the experimental table, can be pulled taut and used to mark this range along the Nd:YAG optic axis. An adjustable flat mirror, positioned at the proper range, will simulate a target for alignment purposes. This mirror can be used to point HL1's beam (and the Nd:YAG optic axis) back at an unoccupied region of the experimental table immediately to the right of the

Fig. 4.1. Schematic for Co-Alignment of HL1 and Nd:YAG Beampaths

Fig. 4.2. Displacement of the Reference Beam
at the Trigger Photodiode

microscope slide (see Fig. 2.1). The collecting telescope and the signal photodiode will lie along this new beampath.

The alignment of this focusing telescope and the signal photodiode is, by far, the most complicated part of this total procedure. The first step requires that a second HeNe laser, to be called "HL2," be installed to the right of the Nd:YAG laser. This HeNe, when adjusted in both position and angle, can be co-aligned with the beam from HL1. The two red beams will thus be traveling in opposite directions down the same optic axis, and will both illuminate the same spot on the target mirror. The telescope now needs to be installed so that its own optic axis is co-aligned with that of HL2. This fine alignment is complete when two criteria are met. The first is that HL2's transmitted beam, although focused by the telescope, must still be co-aligned with the beam from HL1. The second criteria is more subtle. Some element within the telescope partially reflects HeNe light. As a result, Newton's rings are produced about the output aperture of HL2. The second criteria requires that these rings be centered on the aperture. When these two criteria are simultaneously met, the telescope is well aligned for a specific focus setting.

Normally, the focus of the telescope should not affect its alignment. Unfortunately, that is not true of the particular instrument used. The telescope's optic axis, it was discovered, changes slightly in angle as the focus is driven from one extreme to the other. In the interest of time, the telescope's focus setting was optimized; this is described below. Once the focus was optimized, the telescope was re-aligned and then left untouched throughout the course of the LRCS measurements.

The choice of focus setting for the telescope must satisfy two criteria:

- 1) it must be close enough so that the largest target sphere is within the detector's field of view, and
- 2) the focus setting must be far enough so that the signal out of the telescope does not overfill the detector.

This second criteria is the more serious, because the sphere size can always be reduced to accomodate a small field of view.

The telescope's output lens is 5.00 mm in diameter but the detector's active region is only 2.54 mm in diameter. Therefore, every effort must first be made to always guarantee that the captured signal that exits the telescope converges at least to this 2.54 mm diameter circular region. Should the signal overfill the detector, the measured LRCS will be erroneously low. A simple criteria exists for identifying which of these two situations exist. In order to implement it, HL2's beam will have to be temporarily blocked by the installation of a signal detector and an appropriate collection of neutral density filters. Once installed and visually centered on the telescope's output, signals can immediately be recorded and displayed on the storage oscilloscope. By maximizing the displayed signals, the photodiode can then be finely aligned in the plane perpendicular to the telescope's optic axis. When this is done, install the -600 mm diverging lens at the Nd:YAG laser's output, and align it in translation and angle by also maximizing the displayed signal. The converging signal that exits the telescope has an ever shrinking spot size as it approaches its own focus. As the detector is further and further removed from the telescope, it captures more and more of this shrinking spot until finally, it measures all of it.

Beyond this point, the maximized signal strength remains constant as the detector moves through the converging signal's focus. At the focus itself, a small amount of ringing can be observed on the displayed waveform as a local region of the photodiode is driven non-linearly by the concentrated signal. Knowing these techniques, the maximum telescope focus setting which does not overfill the detector's active region can then be determined. For this setting, the detector's field of view now requires closer examination. This is accomplished using a white index card, which, it is found, is a strong, almost Lambertian scatterer at $\lambda = 1.064 \mu\text{m}$. The signal from the index card is much greater than that of the largest sphere but far less than that of an aligned specular mirror. The target mirror should therefore be replaced with the largest sphere which is 1.587 cm in radius and is supported by a specially made lucite rod. Using the detected signal size as a measure of the alignment, adjust the three dimensional location of the sphere to maximize the collected return. When this has been done, one point on the surface of the sphere will intercept both the Nd:YAG's and the telescope's optic axis. Starting inches below the bottom of the sphere, slowly move the edge of the index card up the lucite support rod. As the index card moves within both the spatial limits of the incident pulse and the telescope's field of view, the detected return signal increases dramatically. Fortunately, the field of view is found to just include the 1.587 cm (radius) sphere. This was easily verified by removing the sphere from the lucite rod; the rod, whose position had not changed, contributed a small but distinct reflection that the detector was able to measure. By lowering the rod 1/8 inch, that return disappeared.

The work done so far is generic to all of the measurements. It is at this point in the alignment sequence that a specific target sphere must be properly positioned for measurement purposes. For this reason, all alignment techniques described in the following paragraphs will need to be repeated whenever one sphere is replaced with another.

Procedures Required for the Alignment of Each Sphere. For a telescope with a constant field of view, there is one specific error which grows as the ball size shrinks. That error involves the magnitude of the "background" signal due to the lucite support rod. As smaller and smaller spheres are measured, more and more of the lucite rod is required to enter the telescope's fixed field of view. This is so that each ball can be properly supported in a position centered on the Nd:YAG optic axis. For smaller and smaller spheres the ratio

$$\epsilon = \frac{\text{SIGNAL CONTRIBUTED BY THE ROD}}{\text{SIGNAL CONTRIBUTED BY THE SPHERE}} \quad (36)$$

grows. This is true in spite of the fact that lucite rods of reduced size have been purposely used to support most of the smaller balls. The specific effects described here can be seen by inspecting the data in Chapter V as a function of sphere radius.

The alignment of each ball bearing is complicated by this error. Since the premier technique involves maximizing the return signal amplitude for each adjustment mode, some compensation must be introduced to offset the effect of the lucite rod. The issue is not that the effect of the rod should be measured and then subtracted from the total signal. Instead, the issue is that the sphere will sit much too high,

with respect to the Nd:YAG optic axis, at the completion of the alignment. The solution to this problem involves heavy reliance on HL2. With the signal photodiode removed, HL2's beam focuses through the telescope to a clean, well-defined 1/4" diameter spot at the designated range of 731.5 cm. Since this alignment process is most important for the smaller spheres, the size of the HeNe spot is ideal. They can be easily centered about such a spot. For those ball bearings which are smaller than the 1/4" spot, an examination of the near field shadow will provide sufficient resolution by which to perform the alignment. It should be emphasized that this technique is only 100% valid for adjustments in the vertical axis; this is because unsymmetric reflections occur in the plane containing both the incident and reflected Nd:YAG optic axis (refer to Appendix A). When the sphere has been properly adjusted in elevation, the photodiode should once again be re-installed and aligned to the position of greatest measured return signal. Then, adjustments to the sphere's location in the two remaining axis may be completed. This concludes the preparatory process. Although quite time consuming, the procedures lead to repeatable results provided the sphere has not been re-oriented on the lucite post. This is demonstrated in Chapter V's data section. Before any serious quantitative measurements are recorded, the Nd:YAG laser and the two data recording devices should be allowed to operate for at least one half hour. This warm-up period is merely precautionary.

The Measurement Process

Once the experiment is properly prepared, it is straightforward to conduct. Because of the record of reliable performance earned by the

FND-100 photodiode, the primary source of inconsistencies in this process is the Nd:YAG laser. In order to better deal with those variations, 20 measurements will be made under identical conditions for every data point required. Any of the 20 measurements which deviate from the rest of the group by more than 15% will be disregarded. The rest of the group will be statistically averaged to generate the required data point plus or minus its standard deviation.

The characteristic effect of detector noise on the measured signals can now be calculated. The performance characteristics of the FND-100 photodiode are presented in Table 2.2. The definition of Noise Equivalent Power (NEP) is

$$NEP = \frac{(E_e)_{RMS} \times A_d}{\left(\frac{V_{sig}}{V_{noise}} \right)_{RMS}} \quad (37)$$

where

$(E_e)_{RMS}$ = the incident irradiance (RMS value)

A_d = active area of the detector

= 5.1 mm²

$\left(\frac{V_{sig}}{V_{noise}} \right)_{RMS}$ = the RMS Signal-to-Noise Ratio

(Hengehold, 1985:99). Since this detector's NEP is quoted to be 2.9×10^{-13} Watts, the effective signal-to-noise ratio is

$$\left(\frac{V_{sig}}{V_{noise}} \right)_{RMS} = (3.4482 \times 10^{12}) \times P \quad (38)$$

where

P = incident Power (in units of watts) on the detector (RMS value)

Although the power, P , is not known, it should be fairly large because

of the short pulsewidth. The signal-to-noise ratio should therefore be tremendous in size; furthermore, the very small dark current generated (less than 100 nanoamperes) will not cause an error which is even measurable on the lower millivolt scales. The largest error introduced to the measurement by this choice of detector is actually found in the form of the internal amplifiers which support the data recording instruments. These types of errors are not pertinent to the experiment, though; they primarily affect the response time of the trace and, in fact, have little effect on the displayed amplitudes (when in the millivolt range) (Tektronix, 1983:1-11).

For every optical pulse emitted by the laser, a temporal profile is recorded on the Storage Oscilloscope. An example is presented in Fig. 4.3. It represents a return from a .635 cm radius ball bearing and would be documented as having a peak amplitude of 640 ± 20 millivolts. A similar profile from the EG&G Signal processor is provided in Fig. 4.4.

V. Experimental Measurements and Analysis

This chapter is organized into two major sections. The first section presents all of the measured data from the experiment. This includes the maximum signal amplitudes caused by each of the 13 target spheres, together with their supporting rods. Furthermore, the effect of the rods, once the spheres have been removed, is also documented. The second section comprises an analysis of the data which is tabulated in the first section. A comparison will be made between these experimental results and the theoretical predictions that are listed in Appendix B.

Measurements

The measurements are presented in Tables 5.1 through 5.13. Each table contains eighty different measurements, divided into four groups of twenty, and each of the eighty measurements are made for the exact same position of the lucite support rod. This rod, while holding any one particular sphere, is aligned in a position that is unique to that sphere. The first three columns in Tables 5.1 through 5.13 each represent a new orientation of the ball bearing on the rod. The values within any column, therefore, change only as the laser performance changes. The extent that the laser's output intensity has varied is reflected by the standard deviation calculated at the bottom of each column. The mean values for each column are also calculated and are listed at the bottom of each table. Within any particular table, a comparison of the first three column's average values provides some

insight into the uniformity of the specific sphere's surface. The fourth column in each of these tables measures the effect of just the rod, once the sphere has been removed.

In order to better comprehend the repeatability of the alignment process described in Chapter IV, certain measurements were made three additional times of the 0.635 cm radius sphere. In all three cases, the sphere's orientation on its support rod was not changed in any manner. In each case, however, the rods (and the balls resting on them) were mis-aligned in all three axis, and then re-aligned, before any measurements were made. The results of these independent measurements are featured in Table 5.14.

Analysis of the Results

In order for these results to be easily compared with the theoretical predictions of Appendix B, Tables 5.1 through 5.13 need to be condensed into a more palatable form. This is accomplished in Table 5.15. Here, the difference between the largest mean value for both rod and sphere, and the mean value for the rod alone, is tabulated. The choice of the "largest" mean value is predicated on the following rationale. If the sphere's surface is perfect, these "mean" terms will always be statistically equal. With a large enough number of repeated measurements, the change in laser performance will always average out. But no part of the sphere's surface is perfect; each mean value represents the performance of a local surface element on the sphere. By choosing the "largest" mean value, only the best of these three localized regions is considered in the comparison. As it turns out, the "best" of the three regions may not be very good at all. Looking

specifically at data in Table 5.1, the three different orientations of the 1.587 cm sphere resulted in significant variations in captured signal. If the lowest of the three values (i.e., 2.482 V) is the result of some local damage to the sphere's surface, then it certainly should not be considered. Damage to some of the spheres is present in the form of corrosion. In particular, 5 of the 13 spheres have suffered from pitting in their surfaces which is visible to the naked eye. This was known before any of the measurements were conducted, and every attempt was made to orient these surface defects as far from the Nd:YAG optic axis as possible. The most severe damage is present on the 1.587 cm sphere (see Fig. 5.1). This photo, at a magnification of $\sim 57\times$, details some of the less massive reaction sites on the surface. The smaller sites were chosen for documentation because of two reasons:

- 1) there was much higher contrast in these photos than there was in photos of serious damage in which most of the surface was black.

- 2) The small sites are probably more significant since the more extensive problem areas were purposefully kept far from the optic axis. As a convenient reference, Fig 5.2 is provided, also at a magnification of $\sim 57\times$. The separation between adjacent tick marks is 0.1 mm. Using this scale, the damage in Fig. 5.1 is found to occupy greater than 0.05 mm² of surface area within this camera's field of view. Even more significantly, Fig 5.1 exposes the random dense array of deep gouges and scratches which mar the surface. These were most likely created during the cleaning process. As chemical residue from the corrosion separated from the sphere during cleaning, it served to act as an abrasive under the alcohol soaked lens tissue. Although a more quantitative evaluation of the damage was not possible, this sphere certainly has a high

Fig. 5.1. Representative Photo of Mild Surface Corrosion on 1.537 cm Sphere (magnification $\approx 57X$).

scattering surface. Even if no corrosion had been present, a surface this scratched probably would not perform in quite the manner the geometric model dictates.

Four other spheres suffered, to a lesser degree, from corrosion. The 1.349 cm, 1.191 cm, and 0.873 cm spheres all fit into the same category, with damage that is best considered mild. The fourth sphere, 0.556 cm in radius, has small local damage sites that all are located within the same hemisphere. Careful positioning of the sphere before each measurement eliminated their effect. All the spheres were examined under the microscope; the smaller they were, the more difficult they were to properly photograph. Those which have not yet been mentioned in

Fig. 5.2. Linear Millimeter Scale (Magnified at ~57X)

this section have a good surface quality; coincidentally, they were never cleaned.

In Chapter IV (pg. 51), it was noted that as smaller and smaller spheres are supported by the same rod, the return signal from just that rod must increase. This effect can now be observed from the data in Table 5.15. The five largest ball bearings are each supported by the same lucite rod. Within that group, the rod's return signal size grows as the sphere's radius decreases. This group characteristic is true for all the rods. The reason that there is a discontinuity transitioning from one group to the next is that successive groups use smaller rods. Rod #1 is .0714 cm in diameter. Rod #2 is 0.397 cm in diameter. Rod #3 is 0.238 cm in diameter. Finally, Rod #4 is 0.119 cm in diameter.

The second page in Chapter III introduced the commonly accepted definition of the LRCS of a perfect specular sphere. Accordingly,

$$\sigma_L (\text{SPHERE}) = \pi a^2 \quad (9)$$

The practical use of such a sphere as a calibration standard implies that the measured return signal amplitude should vary primarily as a function of a^2 . This will now be verified. Fig. 5.3 compares the theoretical linear relationship between σ_L and the return signal amplitude, with the actual measured values. The solid line in the figure represents the predicted relationship based on geometric theory, while the individual points represent the measured values. These values, although low, do tend to lie along a straight line provided that the data points representing the two largest and the two smallest spheres are disregarded. The predictions themselves may be high if the absorption within the collecting telescope is much more than the 2% assumed earlier. If, for instance, the absorption was 7.3%, the predicted line in Fig. 5.3 would sink to within 1% of six of the seven relevant data points. The errors associated with the four spheres that comprise both ends of the measurement scale can be explained. The two largest spheres have suffered noticeable surface damage. Although this is sufficient cause for disqualification of these spheres as serious calibration standards, surface corrosion alone might not properly account for the unexpectedly low signals measured from these two spheres. There is reason to suspect that the photodiode used for signal detection may have been operating in its non-linear regime when it outputted such large currents (displayed as voltage amplitudes) during the measurement of these two spheres. This possibility was not recognized until well after

the experiment had been concluded. The two smallest spheres are also plagued with a serious, but different, problem. Because of their miniature size, the lucite rod common to both should be replaced with a different support structure with an even lower LRCS. Because the smallest rod has a return signal of comparable size to the spheres, it is more difficult to accurately separate the two effects.

Unfortunately, the size of the numeric values in this range are so small that even little errors can devastate the accuracy required of a calibration standard. It is therefore going to be recommended that such small spheres not be used as standards.

Fig. 5.3. Comparison of Predicted and Measured LRCS Values for the Spherical Standards (each data point annotated with its relevant sphere's radius)

VI. Conclusion

A LRCS Measurement Range has been designed and constructed to investigate the return signal from highly specular spheres. This was done according to the format presented in Chapter II. An analytic model of the experiment, based on geometric theory, was developed in Chapter III and its predictions were calculated. The laborious process of properly preparing the experimental set-up is critical to the accuracy of these absolute measurements. This preparatory process, and other useful error-reducing steps are reviewed in Chapter IV. The final LRCS measurements are presented in Chapter V, and an analysis of these results is performed within the context of the geometric model's predictions. This chapter capsulizes the important highlights and results of this research, and recommends areas for further study.

Discussion of the Research

The specular sphere can be an excellent standard for the calibration of a LRCS measurement range. However, much effort should first be dedicated to a thorough investigation of this standard's optical quality. Imperfections and inhomogeneties in the sphere may or may not affect the final results, but they will certainly increase the uncertainty assessed to the final data. Furthermore, sufficient effort should be invested to guarantee that the signal detector, chosen to perform these LRCS measurements, is operating within its linear region. Non-linear performance, unlike operation near the detector's saturation level, is not apparent from the temporal profile displayed on the CRT screen of the data collection equipment. In other words, great care

must be used to prevent this otherwise invisible error from being introduced to the final data.

The premier conclusion of this effort is that the maximum amplitude of the return optical signal from a sphere varies as a function of the square of the sphere's radius. This experimental data confirms that the universal definition for a sphere's LRCS (i.e., $\sigma_L = \pi a^2$) is valid, and, in fact, could just as correctly be replaced by any other function of a^2 . Geometric Theory, within the limits of the experiment, has been shown to properly predict the amount of optical energy that can be expected at a detector after scattering from a specular sphere. The theory's dependence on very small angles is not as much a limitation as it is a warning that very tight tolerances on alignments will be required if accuracy is desired.

This measurement process has demonstrated both consistency and repeatability. An improved experimental version should include the necessary hardware to temporally measure a sample of the laser's outgoing wavefront. By monitoring the laser's performance during each run, greater accuracy will be achieved and fewer measurements will be required in order to properly interpret the results. Further recommendations include a suggestion that the experiment be re-designed to measure return signals from a sphere as a function of the bistatic angle, i.e., as a function of the detector's distance from the Nd:YAG laser's optic axis. This type of measurement might reveal that under certain conditions, the geometric optics model is insufficient. A different approach to the same problem would involve expanding on the work already done in Appendix C. The Huygens-Fresnel Theory has been applied rigorously to the problem of scattering from a sphere. A

mathematical description of the reflectivity at every point on the sphere would be required. This description would have to account for phase changes on reflection, incident polarization of the laser beam, and the angle between the surface normal and the polarization vector. If this function were known, the backscattered intensity could then be calculated.

The measurement of a laser radar cross-section is a very difficult task. The interpretation of the results quickly becomes complicated if the target is other than a simple shape. Nonetheless, the simple shape is the building block upon which more complex target shapes are modeled. In much the same way, the sphere has proven itself. By virtue of its simplicity, it can be, if well cared for, an excellent standard for all other LRCS measurements.

Appendix A: Examination of the Relationship
Between r_o and ρ

In Chapter III, small angle approximations were used to derive Eq (28), which is re-written below:

$$\rho = \frac{a r_o}{2 z_i - a} \quad (28b)$$

where

ρ = the normal distance between the z-axis and any point on the sphere

a = the sphere's radius

z_i = the distance between the sphere's center and the observation plane

r_o = the normal distance between the z-axis and any point in the observation plane

This linear relationship would be destroyed if the experiment considered values of r_o which were much larger than ρ . This effect can be easily demonstrated. For values of z such that $a \geq z \geq \frac{a}{2}$,

$$\tan 2\theta \approx \frac{r_o - \rho}{731.5} \quad (39)$$

$$2\theta \approx \tan^{-1} \left(\frac{r_o - \rho}{731.5} \right) \quad (40)$$

$$\frac{d}{dr_o} (2\theta) \approx \frac{d}{dr_o} \left[\tan^{-1} \left(\frac{r_o - \rho}{731.5} \right) \right] \quad (41)$$

$$2 \frac{d\theta}{dr_o} \approx \left[1 + \left(\frac{r_o - \rho}{731.5} \right)^2 \right]^{-1} (731.5)^{-1} \quad (42)$$

Referencing Eq (22)

$$\theta = \sin^{-1} \left(\frac{\rho}{a} \right) \quad (43)$$

$$\frac{d\theta}{dr_o} = \left(1 - \frac{\rho^2}{a^2} \right)^{-1/2} \frac{d}{dr_o} \left(\frac{\rho}{a} \right) \quad (44)$$

$$= (a^2 - \rho^2)^{-1/2} \frac{d\rho}{dr_o} \quad (45)$$

Therefore, Eq (42) reduces to

$$\frac{d\rho}{dr_o} \approx \frac{(a^2 - \rho^2)^{1/2}}{2 \left\{ 731.5 + \left[(r_o - \rho)^2 / 731.5 \right] \right\}} \quad (46)$$

and

$$\frac{dr_o}{d\rho} \approx \frac{1463 + (r_o - \rho)^2 / (365.75)}{(a^2 - \rho^2)^{1/2}} \quad (47)$$

Eq (47) indicates that as ρ increases, the rate of growth of r_o increases even faster; this is because of the decreasing size of the denominator. It is only when r_o and ρ are of comparable size (i.e., when both have very small values) that $dr_o/d\rho$ is effectively constant. Within the context of Chapter III's discussion, it is when the derivative is no longer constant that the sphere's effective area deviates from a circle. The distortion occurs radially about the z-axis and would cause a

circular area (not centered on the z-axis) to become egg-shaped.

Appendix B: Signal Size Predictions for the 13 Test Spheres

Using the geometric optics model presented in Chapter III, the peak amplitudes (in units of "volts") expected from each of the spheres can be calculated. The energy measured by the photodiode (within its linear operating region) is proportional to the magnitude of the signal it emits; therefore, Eq (11) can be modified to read

$$V_{\text{EXPECTED}} = \chi A_{\text{eff}} \Gamma \eta T \quad (48)$$

where

V_{EXP} = the voltage measured by the data collection equipment

χ = a convenient term for the measured energy density (in units of V/cm^2)

A_{eff} = effective surface area of the sphere, projected onto a plane, which re-radiates measured energy

Γ = reflectivity of the sphere at $1.064 \mu\text{m}$
= .98

η = round trip attenuation of the laser energy by the atmosphere
= .99

T = transmissivity of the telescope at $1.064 \mu\text{m}$
= .98

The evaluation of χ is straight-forward. Fig. 2.5 plots the local irradiance distribution within the flatter, central region of the typical laser pulse. The maximum recorded magnitude is 23.0 Volts, and it can be found in two separate regions almost 2 cm apart. The smallest magnitude measured between these two peak regions is 20.0 Volts. In order to maintain some analytical continuity across this region, all points with magnitudes of 20.0 Volts or greater will be considered to be

part of the incident plane wave. The average of these 139 measurements is 21.01 Volts. When this data was accumulated, an attenuation filter was used to ensure a linear response from the photodiode. Because of it, the corrected average signal voltage is 175.08 V. This value represents the signal from an obscured detector; the .20 mm slit only exposes an active area of

$$(0.20 \text{ mm})(2.54 \text{ mm}) \approx .508 \text{ mm}^2 \quad (49)$$

Scaling this signal appropriately determines χ :

$$\chi = \frac{175.08 \text{ V}}{.508 \text{ mm}^2} = 3.44 \times 10^2 \text{ V/mm}^2 \quad (50a)$$

$$\chi = 3.44 \times 10^4 \text{ V/cm}^2 \quad (50b)$$

The final calculation of V_{expected} depends only on the computation for A_{eff} for each value of a , the sphere's radius. An example of this is presented in Chapter III by Eq (29a) through Eq (32). The results of this effort are listed in Table B.1.

Table B.1.

Signal Size Predictions

"a," the sphere's radius (cm)	A_{eff} (cm ²)	V_{expected}	
		(volts)	(Millivolts)

*. . . N/R = "Not Relevant"

Appendix C: Rigorous Application of Physical Optics

Using an analytic development somewhat similar to Erteza's (Erteza, 1981:1002-1007), the Huygen's-Fresnel principle can be expanded upon in order to calculate the local field amplitude for each individual point in the observation plane. By integrating over the telescope's entrance aperture, the total energy incident upon the detector can be calculated. The small angle approximations extensively relied on in Chapter 3 will not be used; to do so would be to deny the possible effects that points on the sphere, far from the optic axis, might have.

The plane wave of constant irradiance which is incident on the sphere is represented by

$$\tilde{u}(z) = A \exp [jk(z_i - z)] \quad (51)$$

where

$\tilde{u}(z)$ = the complex amplitude of the field

A = the amplitude of the incident field

= a constant

k = the wavenumber, $2\pi/\lambda$

z_i = the location of the observation plane along the z-axis

z = the axis along which the wavefront propagates

The irradiance of this field, measured in W/cm², is also a constant, I_0 , and can be represented by

$$I_0 = |A|^2 \quad (52)$$

The problem is depicted in cylindrical coordinates in Fig. C.1. Breaking with standard convention, this incident wavefront will propagate from right to left, in the negative z -direction. The saving grace in this choice is the fact that, upon reflection, the scattered return field travels in the correct direction, from left to right, as tradition would have it. Every point (ρ, \varnothing, z) on the illuminated portion of the sphere can be thought of as a point source whose contribution is weighted according to its distance from the z -axis. Using Gaskill's nomenclature, the complex amplitude of the backscattered field due to the point (ρ, \varnothing, z) is

$$\tilde{u}'(\rho, \varnothing, z) = \eta R(\varnothing, \varnothing)(\cos \varnothing) \tilde{u} \quad (53)$$

where

$$\tilde{u}'(\rho, \varnothing, z) = \tilde{u}'(z)$$

= . . . note: the "prime" indicates that reflection from the sphere has occurred.

η = the round trip attenuation of the laser pulse's energy by the atmosphere

$R(\varnothing, \varnothing)$ = the reflectance of any specific point on the sphere's surface at $1.064 \mu m$

$\cos \varnothing$ = an obliquity factor, or a form of "directional reflectivity"

(Gaskill, 1978:354). Both Goodman and Danielson also discuss the use of an obliquity factor as a "directivity pattern" for each secondary source (Goodman, 1968:42 Danielson, 1977:7). Because the incident plane wave is linearly polarized, the phase shifts arising upon reflection are not just functions of the angle of incidence, \varnothing . "The phase shift occurs in

CYLINDRICAL COORDINATES

Fig. C.1. Three Dimensional Analysis of the Scattering Problem Within the Realm of Physical Optics
(not drawn to scale)

both components of the field (i.e., parallel and perpendicular to the plane of incidence," (Hecht and Zajac, 1979:89). Since the plane of incidence changes as a function of θ , the phase shift must vary accordingly. The reflectance R of the metal therefore depends on both θ and ϕ (i.e., on the specific reflecting point on the sphere's surface). The term R will contain the phase shift and will remain unspecified throughout the rest of this development.

Rewriting Eq (53)

$$\tilde{u}'(z) = A R(\theta, \phi) \eta \cos \theta \cdot \exp[jk(z_i - z)] \quad (54)$$

Using the mathematical expression of the Huygens-Fresnel principle, the field amplitude (r, γ, z_i) can be determined (Goodman, 1968:58):

$$\tilde{u}'(r, \gamma, z_i) = \iint_{\text{SURFACE}} h \cdot \tilde{u}'(\rho, \phi, z) dS \quad (55a)$$

$$h = \frac{1}{j\lambda} \frac{\exp[jkR]}{R} \cos(\bar{n}, \bar{R}) \quad (55b)$$

where

h = a weighting function

dS = a two-dimensional surface element at (ρ, ϕ, z)

\bar{R} = the vector, assumed positive, which connects the surface point to the observation point

\bar{n} = the unit normal vector at (ρ, ϕ, z)

Substituting Eq (54) and (55b) into Eq (55a):

$$\tilde{u}'(r, \gamma, z_i) = \iint_{\text{SURFACE}} \frac{A R \eta}{j\lambda R} \exp[jk(z_i - z) + jkR] \cos \theta \cos(\bar{n}, \bar{R}) dS$$

Referring to Fig. C.1, the following identities can be written:

$$\cos \theta = \frac{z}{a}, \longrightarrow z = a \cos \theta \quad (56)$$

$$\sin \theta = \frac{\rho}{a}, \longrightarrow \rho = a \sin \theta \quad (57)$$

Therefore

$$\begin{aligned} \tilde{u}'(r_o, \gamma, z_i) = & \frac{A\eta}{j\lambda R} \iint_{\text{SURFACE}} \exp [jkz_i - jk a \cos \theta + jk R] \\ & \times R(\theta, \vartheta) \cos \theta \cos(\bar{n}, \bar{R}) dS \end{aligned} \quad (58)$$

Using the Fresnel approximation, i.e., that $R \approx Z_i$ when R is not multiplied by a very large factor (as it is in the exponent).

$$\begin{aligned} \tilde{u}'(r_o, \gamma, z_i) = & \frac{A\eta}{j\lambda z_i} \iint \exp [jk(z_i - a \cos \theta) + jk R] \\ & \times R(\theta, \vartheta) \cos \theta \cos(\bar{n}, \bar{R}) dS \end{aligned} \quad (59)$$

But

$$dS = a \cos \theta d\theta \rho d\vartheta \quad (60a)$$

Fig. C.2. Geometric Representation of \bar{R}

Fig. C.3. Enlargement of the Observation Plane Represented in Fig. C.2
(not drawn to scale)

Fig. C.4 A Further Refinement of Fig. C.3
(not drawn to scale)

$$dS = a^2 \cos \theta \sin \theta \, d\theta \, d\phi \quad (60b)$$

An exact geometric representation of R is still required. Solving in terms of the simple geometry of right triangles (see Figs. C.2-C.4), values of x and of y must first be determined. From Fig. C.3,

$$\cos(\varnothing - \gamma) = \frac{r_o - x}{\rho} \quad (51a)$$

$$r_o - x = \rho \cos(\varnothing - \gamma) \quad (61b)$$

$$x = r_o - \rho \cos(\varnothing - \gamma) \quad (61c)$$

Thus

$$y = \left[\rho^2 \sin^2(\varnothing - \gamma) + r_o^2 + \rho^2 \cos^2(\varnothing - \gamma) - 2 r_o \rho \cos(\varnothing - \gamma) \right]^{1/2} \quad (62a)$$

$$y = \left[\rho^2 + r_o^2 - 2 r_o \rho \cos(\varnothing - \gamma) \right]^{1/2} \quad (62b)$$

Finally, the geometric distance between the surface point and the observation point is determined by the right triangle which has R for a hypotenuse, and y and $(z - z_i)$ for legs.

$$R^2 = (z_i - z)^2 + y^2 + r_o^2 - 2 r_o \rho \cos(\varnothing - \gamma) \quad (63)$$

It is here that the Fresnel approximation can be used. Re-writing R :

$$R = (z_i - z) \left\{ 1 + \frac{1}{(z_i - z)^2} \left[r_o^2 + \rho^2 - 2 r_o \rho \cos(\varnothing - \gamma) \right] \right\}^{1/2} \quad (64a)$$

The allowed approximation is of the form

$$(1+b)^{1/2} \approx 1 + \frac{b}{2} \quad (64b)$$

provided that the next term in the series, $b^2/8$, is very small compared to unity. This can be readily verified by examining the maximum value of b under all of the worst conditions. These worst conditions include:

$$\cos \theta = 1 \quad (65a)$$

$$r_s = 22 \quad (65b)$$

$$\rho = 2.7 \quad (65c)$$

$$z_i = 731.5 \quad (65d)$$

$$z = 2.7 \quad (65e)$$

$$(z_i - z)^{-2} = 1.9 \times 10^{-6} \quad (65f)$$

$$b_{\max} = 7.0773 \times 10^{-4} \quad (65g)$$

The criteria for use of Eq (50b) is therefore met because

$$\frac{b^2}{8} = 5.0088 \times 10^{-7} \ll 1 \quad (65h)$$

Therefore

$$R \approx (z_i - z) \left\{ 1 + \frac{1}{2(z_i - z)^2} [r_s^2 + \rho^2 - 2r_s \rho \cos(\theta - \gamma)] \right\} \quad (66a)$$

Because $(z - z_i) \approx z_i$

$$R \approx z_i - z + \frac{1}{2(z_i - z)} [r_o^2 + \rho^2 - 2r_o \rho \cos(\varnothing - \gamma)] \quad (66b)$$

becomes

$$R \approx z_i - z + \frac{1}{2z_i} [r_o^2 + \rho^2 - 2r_o \rho \cos(\varnothing - \gamma)] \quad (66c)$$

and

$$jkR \approx jk(z_i - a \cos \theta) + \left\{ \frac{jk}{2z_i} \times \right. \\ \left. [r_o^2 + a^2 \sin^2 \theta - 2r_o (a \sin \theta) \cos(\varnothing - \gamma)] \right\} \quad (67)$$

Substituting Eq (61b) and (68) into Eq (60) yields

$$\tilde{u}' = \frac{A \eta}{j \lambda z_i} \int_0^{\pi/2} \int_0^{2\pi} a^2 (\cos^2 \theta) (\sin \theta) [\cos(\bar{n}, \bar{R})] \times \\ R(\theta, \varnothing) \exp \left\{ 2jk(z_i - a \cos \theta) \right. \\ \left. + \frac{jk}{2z_i} [r_o^2 + a^2 \sin^2 \theta - 2a r_o \sin \theta \cos(\varnothing - \gamma)] \right\} d\varnothing d\theta \quad (68)$$

A new representation of $\cos(\bar{n}, \bar{R})$ is necessary. The angle between \bar{n} and \bar{R} will now be referred to as β . The relationship between β and θ must be established so that the integration over \varnothing and θ may be completed. In the coordinate system used to date, this problem would be three-dimensional. In order to simplify it to two-dimensions, the single plane containing both the vectors \bar{n} and \bar{R} (see Fig. C.5) must be identified. The three points that describe this plane are: (in

Fig. C.5. Geometry of the Plane Containing the Vectors and

cylindrical coordinates), $(0,0,0)$, (ρ, ϕ, z) , and (r, γ, z) . Using the law of cosines, a relationship between each of the sides and the angle β can be written:

$$(z_i^2 + r_i^2) = (a)^2 + (R)^2 - 2(a)(R) \cos(\pi - \beta) \quad (69)$$

$$z_i^2 + r_i^2 - a^2 - R^2 = -2aR \cos(\pi - \beta) \quad (70a)$$

$$\frac{z_i^2 + r_i^2 - a^2 - R^2}{2aR} = -\cos(\pi - \beta) \quad (70b)$$

but $\cos(\pi - \beta) = -\cos \beta$. Therefore

$$\frac{z_i^2 + r_i^2 - a^2 - R^2}{2aR} = \cos \beta \quad (71)$$

Manipulating Eqs (56) and (57), it can be shown that

$$z^2 + \rho^2 = a^2 \cos^2 \theta + a^2 \sin^2 \theta$$

$$z^2 + p^2 = a^2 (\cos^2 \theta + \sin^2 \theta) = a^2 \quad (72)$$

Substituting Eqs (63) and (72), into Eq (71)

$$\cos \beta = \frac{z_i^2 + r_o^2 - a^2 - (z_i - z)^2 - p^2 - r_o^2 + 2 r_o p \cos(\phi - \gamma)}{2 a R} \quad (73a)$$

$$\cos \beta = \frac{z_i^2 - a^2 - z_i^2 + 2 z z_i - (z^2 + p^2) + 2 r_o p \cos(\phi - \gamma)}{2 a R} \quad (73b)$$

$$\cos \beta = \frac{-2 a^2 + 2 z z_i + 2 r_o p \cos(\phi - \gamma)}{2 a R} \quad (73c)$$

Substituting Eq (66c) into the denominator

$$\cos \beta = - \frac{2 a^2 - 2 z z_i + [-2 r_o p \cos(\phi - \gamma)]}{2 a \left\{ z_i - z + \frac{1}{2 z_i} [r_o^2 + p^2 - 2 r_o p \cos(\phi - \gamma)] \right\}} \quad (73d)$$

This substitution was made now so that the form of the denominator could be observed. Since no further manipulation of the terms in this substitution is expected, future equations will again refer to the denominator's bracketed term as R. The process of integration over ϕ will be greatly simplified if the cosine term containing ϕ can be eliminated from the numerator. This was the objective hidden in the substitution of an approximation for R in the denominator but not in the numerator. By manipulating the numerator so that it resembles the denominator, the cosine term in the numerator can be cancelled.

$$\cos \beta = - \frac{2a^2 - 2zz_i + [r_o^2 + \rho^2 - 2r_o \rho \cos(\phi - \gamma)] - r_o^2 - \rho^2}{2aR} \quad (74a)$$

$$= - \left(\frac{1}{\sqrt{2z_i}} \right) \left\{ \frac{(2a^2 - 2zz_i - r_o^2 - \rho^2) + [r_o^2 + \rho^2 - 2r_o \rho \cos(\phi - \gamma)]}{2aR} \right\} \quad (74b)$$

$$= - \frac{(2z_i)^{-1/2} (2a^2 - 2zz_i - r_o^2 - \rho^2) + (2z_i)^{-1/2} [r_o^2 + \rho^2 - 2r_o \rho \cos(\phi - \gamma)]}{(2z_i)^{-1/2} (2aR)} \quad (74c)$$

$$= - \frac{[(2z_i)^{-1/2} (2a^2 - 2zz_i - r_o^2 - \rho^2) - z_i + z] + R}{(2z_i)^{-1/2} (2aR)} \quad (74d)$$

$$= - \frac{(2z_i)^{-1/2} (2a^2 - 2zz_i - r_o^2 - \rho^2) - z_i + z}{(2z_i)^{-1/2} (2aR)} - \frac{R}{(2z_i)^{-1/2} (2aR)} \quad (74e)$$

$$= - \frac{[2a^2 - 2zz_i - r_o^2 - \rho^2 + 2z_i(z - z_i)]}{2aR} - \frac{z_i}{a} \quad (74f)$$

$$= \frac{2z_i^2 - 2a^2 + r_o^2 + \rho^2}{2aR} - \frac{z_i}{a} \quad (74g)$$

Substituting Eqs (56), (57), and (66c) into Eq (74g), the final form is

$$\cos \beta = \frac{2z_i^2 - 2a^2 + r_o^2 + a^2 \sin^2 \theta}{2a \left\{ z_i - a \cos \theta + \frac{1}{2z_i} [r_o^2 + a^2 \sin^2 \theta - 2r_o a \sin \theta \cos(\theta - \gamma)] \right\}} - \frac{z_i}{a} \quad (75)$$

Fig. C.6. Illustration of the Differential Area
Across Which $I(r_0)$ is Constant in the Plane $z=z_i$

Substituting Eq (75) into Eq (69) yields

$$\begin{aligned} \tilde{u}' = & \frac{A \eta}{j \lambda z_i} a^2 \int_0^{\pi/2} \int_0^{2\pi} (\cos^2 \theta) (\sin \theta) R(\theta, \phi) \times \\ & \exp \left\{ 2jk(z_i - a \cos \theta) + \frac{jk}{2z_i} [r_0^2 + a^2 \sin^2 \theta - 2ar_0 \sin \theta \cos(\phi - \gamma)] \right\} \times \\ & \left\{ \frac{2z_i^2 - 2a^2 + r_0^2 + a^2 \sin^2 \theta}{2a \left\{ z_i - a \cos \theta + (2z_i)^{-1} [r_0^2 + a^2 \sin^2 \theta - 2r_0 a \sin \theta \cos(\phi - \gamma)] \right\}} \right. \\ & \left. - \frac{z_i}{a} \right\} d\phi d\theta \end{aligned} \quad (76)$$

This double integral describes the complex field amplitude at the point (r_0, γ, z_i) . If the real part is then squared, the local irradiance is then obtained. The total irradiance at the telescope's entrance can

then be calculated by integrating $|\tilde{u}'(r_0)|^2$ over the entrance aperture. Setting aside the problem of solving Eq (76), we will now address the question of integrating $|\tilde{u}'(r_0)|^2$ over the aperture.

Let $|\tilde{u}'(r_0)|^2 = I(r_0)$. $I(r_0)$ is a constant value for each of the points along the circumference of the circle of radius r_0 . Since $I(r_0)$ is measured in units of watts per square centimeter, a differential area must be established over which the power can be calculated (see Fig. C.6). If γ were unbounded, then the differential area would be $2\pi r_0 dr_0$. However, since only that differential area within the aperture is of interest, the modified area (the shaded portion in fig C.6) is just $2\gamma r_0 dr_0$. Since γ has a different maximum value for every value of r_0 that connects with the collecting aperture's perimeter, a mathematical relationship must be established between these two terms. Using the law of cosines

$$b^2 = r_0^2 + c^2 - 2r_0 c \cos \gamma \quad (77)$$

where

b = radius of the aperture
 = 5.4 cm (constant)

c = separation between the center of the aperture and the origin
 = 17 cm (constant)

Manipulating Eq (77)

$$\gamma = \cos^{-1} \left(\frac{r_0^2 + c^2 - b^2}{2r_0 c} \right) \quad (78)$$

Thus, knowing the angular limits that define the collecting aperture, and knowing that r_0 is an extreme value at 17.0 ± 5.4 cm, an integral can be written which describes the power incident on the collecting telescope.

It is

$$P_{\text{APERTURE}} = \int_{11.6 \text{ cm}}^{22.4 \text{ cm}} 2 \gamma r_0 I(r_0) dr_0 \quad (79a)$$

$$= \int_{11.6 \text{ cm}}^{22.4 \text{ cm}} 2 r_0 I(r_0) \cos^{-1} \left(\frac{r_0^2 + c^2 - b^2}{2 r_0 c} \right) dr_0 \quad (79b)$$

$$= 2 \int_{11.6 \text{ cm}}^{22.4 \text{ cm}} r_0 I(r_0) \cos^{-1} \left(\frac{r_0^2 + 259.8}{34 r_0} \right) dr_0 \quad (79c)$$

When this power is known, a revised value at the detector can be estimated based on the expected absorptive losses in the telescope. Using Eq (34), the final signal size expected on the data collection equipment can be calculated.

VITA

Captain James C. Higgins was born on 22 July 1958 in Miami, Florida. He graduated from high school in 1976 and attended the University of Notre Dame from which he received the degree of Bachelor of Science in Physics in May 1980. Upon graduation, he received a commission in the United States Air Force through the ROTC program. His first assignment was to the Air Force Weapons Laboratory, Kirtland AFB, New Mexico. While there, he served as an optical physicist for, and a flight crew member on, the Airborne Laser Laboratory. In November 1982, he met Kathy Klattenhoff and in May 1984, they were married. Following the honeymoon, he entered the School of Engineering, Air Force Institute of Technology.

This research effort measured the size of the optical signals scattered by highly specular spheres when illuminated by plane wavefronts. This was repeated for 13 different sized spheres so that the functional dependency on sphere size could be more accurately established. The experiment was conducted at $\lambda = 1.064 \mu\text{m}$ and at a fixed range of 731.5 cm in a bistatic configuration.

An analytical development based on geometric optics was used to predict the results. Within the limits of the small angle approximations, the results were generally within 10% of the measured values. The surface quality of the spheres and the alignment of the experiment were found to be the most critical variables affecting accuracy.
